## Abstract

The kinetic characteristics of electrochemical reduction of  $\text{SiO}_2$  granules in molten  $\text{CaCl}_2$  were investigated to develop a new process for producing solar-grade silicon. The reduction rate was evaluated based on the time dependence of the reduction fractions measured from the growth of the reduced Si layer and the weight change of the samples during electrolysis. The samples were prepared by potentiostatic electrolysis of  $\text{SiO}_2$  granules in molten  $\text{CaCl}_2$  at 1123 K. The results indicated that the reduction was fast at the initial stage of electrolysis, and gradually slowed as the reaction progressed. The apparent current density reached  $0.7 \text{ A cm}^{-2}$  at the initial stage, which was comparable to the commercial Hall-Héroult process for aluminum production.

**Key Words:** Solar-grade Silicon, Silica, Electrolysis, Molten Salt, Kinetics, Current Density

29 **Introduction**

30 The global solar cell market has grown rapidly over the past decade. The annual installation of  
31 solar cells in the world reached 28.6 GW in 2012.<sup>1</sup> Crystalline silicon is the most prevalent raw  
32 material for solar cells on the market, and Si-based solar cells accounted for 88% of the global  
33 production in 2012.<sup>2</sup> With the expansion of the market, the consumption of solar-grade silicon  
34 (SOG-Si; 6N purity) has also climbed dramatically. An average growth of 10–20% per year is  
35 estimated for SOG-Si production over the next decade.

36 The Siemens process,<sup>3-5</sup> based on hydrogen reduction and thermal decomposition of  
37 trichlorosilane ( $\text{SiHCl}_3$ ), is the most widely used process for SOG-Si production. In spite of the  
38 highly reliable product quality, this process has some disadvantages, including low productivity, low  
39 reaction efficiency, and high energy consumption. Therefore, a novel, high yielding, inexpensive  
40 SOG-Si production process is required.

41 Various SOG-Si production processes have been developed to displace the Siemens process.<sup>6-25</sup>  
42 Meanwhile, the authors<sup>26-33</sup> and other researchers<sup>34-43</sup> have demonstrated that solid silica ( $\text{SiO}_2$ ) can  
43 be directly reduced to solid Si via electrolysis in molten salts. A  $\text{SiO}_2$  plate or pellet in contact with a  
44 current conductor is electrochemically reduced to Si at the three-phase zone of  $\text{SiO}_2$ /molten  
45 salt/conductor. The produced  $\text{O}^{2-}$  ions are transferred to the carbon anode through the melt, and then  
46 oxidized to form CO or  $\text{CO}_2$ . The authors has proposed a new SOG-Si production process by

47 combining this method with the use of high-purity silica and directional solidification,<sup>32</sup> and  
48 demonstrated that impurities in the produced Si can be controlled at a low level when high-purity  
49 SiO<sub>2</sub> is used as the raw material.<sup>44</sup>

50 Recently, the authors proposed an improved electrochemical process in which SiO<sub>2</sub> granules are  
51 directly used as the raw material.<sup>45</sup> From the viewpoint of industrial application in the future,  
52 granules have advantages in cost and quality control over plates or pellets, as well as the suitability  
53 for a continuous operation. SiO<sub>2</sub> granules are supplied from the top of the electrolysis cell and are  
54 stratified on the cathode placed at the bottom of the cell. The electrochemically reduced Si in molten  
55 CaCl<sub>2</sub> is tapped out from the cell bottom as slurry containing molten CaCl<sub>2</sub>. The advantage of this  
56 process is the compatibility for a semi-continuous operation, which improves the productivity.

57 The kinetics of the direct electrochemical reduction of solid SiO<sub>2</sub> granules is crucial for the scale  
58 up of the laboratory experiment for commercial production. Previously, the kinetics was studied  
59 based on the current-time curve during electrolysis<sup>45</sup> and direct observation of the reaction  
60 interface.<sup>46</sup> The overall reduction was clarified to proceed via two different routes: (1) from the SiO<sub>2</sub>  
61 granules near the conductor to the distant granules along the granule surfaces, and (2) from the  
62 surface to the core in each partly reduced granule. Formation of the core (SiO<sub>2</sub>)–shell (Si) structure  
63 for partly reduced SiO<sub>2</sub> granules indicated that the reduction along the granule surfaces was faster  
64 than that from the surface to the core.

65 In the present study, the kinetic characteristics of the electrochemical reduction of SiO<sub>2</sub> granules  
66 in molten CaCl<sub>2</sub> at 1123 K were further investigated by the direct measurement of the reaction  
67 interfaces and the weight change of the samples during electrolysis. The kinetics was discussed by  
68 plotting the time dependence of the reduction fraction. The productivity of the proposed process was  
69 evaluated based on the apparent current density calculated from the experimental results.

70

## 71 Experimental

72 An Al<sub>2</sub>O<sub>3</sub> crucible (Nikkato Corp., o.d. 90 × i.d. 80 × height 100 mm) charged with 300 g of  
73 CaCl<sub>2</sub> (Kojundo Chemical Lab. Co., Ltd., 99%) was set inside a SiO<sub>2</sub> vessel and heated to 1123 K in  
74 a dry Ar atmosphere (100 mL min<sup>-1</sup>) in an electric furnace. Prior to the experiment, CaCl<sub>2</sub> was dried  
75 under vacuum at 453 K for 72 h and 773 K for 24 h. The working electrode comprised an Al<sub>2</sub>O<sub>3</sub> tube  
76 (Nikkato Corp. o.d. 13 × i.d. 9 × height 10 mm) and a Si plate (Nilaco Corp., □15.0 × thickness 0.5  
77 mm, n-type, (100) plane, resistivity 0.1–1.0 Ω cm) (Figure 1). A nickel wire (Nilaco Corp., □1.0 mm,  
78 99%) used as the current lead was connected to the Si plate by threading into a drilled hole (□1.1  
79 mm). Approximately 0.41 g of high-purity SiO<sub>2</sub> granules (Taiheiyo Cement Corp., particle size < 0.1  
80 mm) was charged in the Al<sub>2</sub>O<sub>3</sub> tube. With this setup, electrical contact to SiO<sub>2</sub> occurs only through  
81 the Si plate at the bottom of the Al<sub>2</sub>O<sub>3</sub> tube.

Fig. 1

82 A glassy carbon rod (Tokai Carbon Co., Ltd., □5.2 mm) was used as the counter electrode. The

83 reference electrode was a  $\text{Ag}^+/\text{Ag}$  electrode prepared by immersing a silver wire (Nilaco Corp.,  $\phi$ 1.0  
84 mm, 99%) in a  $\text{CaCl}_2$  melt containing 0.5 mol%  $\text{AgCl}$  (Wako Pure Chemical Co., Ltd., 99.5%) in a  
85 mullite tube (Nikkato Corp., o.d.  $6 \times$  i.d.  $4 \times$  height 450 mm). The potential of this reference  
86 electrode was occasionally checked against a  $\text{Ca}^{2+}/\text{Ca}$  dynamic reference electrode, prepared  
87 galvanostatically on a Mo wire (Nilaco Corp.,  $\phi$ 1.0 mm, 99.95%).<sup>31</sup> All potentials are given with  
88 reference to the  $\text{Ca}^{2+}/\text{Ca}$  potential.

89 After immersing the electrodes in the  $\text{CaCl}_2$  melt, the potential of the working electrode was set at  
90 0.5 V vs.  $\text{Ca}^{2+}/\text{Ca}$  for the potentiostatic electrolysis for 10 min to 240 min. The working electrode  
91 was immediately taken out from the melt after electrolysis and a new one was immersed in for  
92 another run. The post-electrolysis working electrode was cut vertically into two halves with a  
93 diamond wheel saw (SBT 650, Meiwafoods Co., Ltd.) to observe the cross section and measure the  
94 thickness of the reduced layer. The kinetics was evaluated by measuring the weight change of the  
95 sample between before and after electrolysis. After electrolysis, the sample was first washed in 1M  
96 HCl for 24 h. Here, byproducts like  $\text{CaSiO}_3$ ,  $\text{CaO}$  and  $\text{CaCO}_3$  react with HCl leaving  $\text{SiO}_2$  as the  
97 only solid residue. Then, the sample was further washed in distilled water for 48 h, and weighed  
98 after drying.

99 Blank electrolysis tests using the working electrodes without charging  $\text{SiO}_2$  granules were  
100 conducted before and during the experiment. Large and unstable background currents (*ca.* -100 mA)

101 were detected, which were mainly due to the side electrochemical reactions of moisture. Since the  
102 area of Si plate contacting only the molten salt was larger than the area contacting SiO<sub>2</sub> granules  
103 (See Fig. 1b), it was difficult to precisely evaluate the current corresponding only to the SiO<sub>2</sub>  
104 reduction.

105

## 106 Results and Discussion

107 **Growth of Reduced Layer.** —The cross sections of the working electrodes after electrolysis at 0.5  
108 V vs. Ca<sup>2+</sup>/Ca for (a) 10 min, (b) 30 min, (c) 60 min, and (d) 120 min in molten CaCl<sub>2</sub> at 1123 K are  
109 shown in Figure 2. For each sample, a dark brown layer was observed above the Si plate at the  
110 bottom. Formation of crystalline Si in this layer was confirmed by XRD and SEM/EDX in a  
111 previous study with a similar experimental setup.<sup>46</sup>

Fig. 2

112 The dark layer, composed of reduced Si, grows from the bottom to the top with the progress of  
113 electrolysis. After 120 min of electrolysis, most of the colorless 6.0-mm-thick SiO<sub>2</sub> layer became

114 dark. The top position of unreduced SiO<sub>2</sub> layer did not apparently change after reduction, as seen in

115 Figure 2. This indicates that the granules piled on the Si plate as a whole do not shrink downward

116 during the reduction. In the similar manner as quartz plate,<sup>26</sup> the volume decrease from SiO<sub>2</sub> to Si is

Fig. 3

117 explained by the formation of porous structure inside the granule. The thicknesses of the dark layer

118 at three different positions for each image in Figure 2 were measured using a ruler. The average

119 value of the reduced layer is plotted against electrolysis time in Figure 3. The growth rate of the

120 reduced layer gradually decreased with the electrolysis progress.

121

122 **Weight Change during Electrolysis.**— The progress of the electrochemical reduction was

123 investigated by measuring the weight change of the samples. The mass balance before and after

Fig. 4

124 electrolysis is illustrated in Figure 4, where  $W_{\text{bef.}}$  and  $W_{\text{aft.}}$  are the weights of the samples before and

125 after electrolysis. Here, the dissolution of solid  $\text{SiO}_2$  in molten  $\text{CaCl}_2$  is not considered. Because the

126 Si atoms remain in the tube during the electrolysis, the weight change occurs by the removal of

Table I

127 oxygen. The weight change after 10–240 min of electrolysis are listed in Table I and plotted against

Fig. 5

128 electrolysis time in Figure 5. In accordance with the growth rate of the reduced layer, the rate of the

129 weight change is large at the initial stage of electrolysis compared with the later stage.

130

131 **Reduction Fraction during Electrolysis.**— The reduction fraction was evaluated by two methods.

132 From the perspective of the growth of the reduced layer, the apparent reduction fraction ( $F_{\text{app.}}$ ) is

133 defined as

$$134 \quad F_{\text{app.}} = \frac{\delta_{\text{red.}}}{\delta_{\text{ini.}}} \times 100\% \quad (1)$$

135 where  $\delta_{\text{red.}}$  and  $\delta_{\text{ini.}}$  are the thicknesses of the reduced layer and the initial  $\text{SiO}_2$  layer (Figure 2).

136 Secondly, the actual reduction fraction ( $F_{\text{act.}}$ ) is calculated from the weight change of the samples

137 during electrolysis by

$$138 \quad F_{\text{act.}} = \frac{(W_{\text{bef.}} - W_{\text{aft.}}) \cdot \frac{M_{\text{SiO}_2}}{2M_{\text{O}}}}{W_{\text{bef.}}} \times 100\% \quad (2)$$

139 where  $M_{\text{SiO}_2}$  and  $M_{\text{O}}$  are the molar weights of  $\text{SiO}_2$  and O, respectively.

140 The apparent and actual reduction fractions are listed in Table II. The time dependences of the

Table II

141 reduction fractions are compared in Figure 6. The apparent reduction fraction was larger than the

Fig. 6

142 actual value. The difference is due to the formation of the core ( $\text{SiO}_2$ )–shell (Si) structure for the

143 partly reduced  $\text{SiO}_2$  granules (Figure 7).<sup>46</sup> The  $\text{SiO}_2$  granules in the reduced layer were not

Fig. 7

144 completely reduced to Si.

145  $F_{\text{app.}}$  and  $F_{\text{act.}}$  rapidly increased at the initial stage of electrolysis as compared with the later stage.

146 This tendency indicates that the reduction gradually slows with the progress of electrolysis, and two

147 potential explanations can be considered. First, contact resistance exists between formed Si particles,

148 resulting in a voltage drop. With the progress of electrolysis, the reduction front gradually moves

149 away from the start point (Si plate) leading to a large voltage loss by contact resistance. The

150 reduction rate has been reported to decrease at more positive potentials.<sup>26,27,29</sup> Because the contact

151 resistance would be primarily generated at the surface of Si granules, this effect plays an important

152 role on the behavior of  $F_{\text{app.}}$ . Moreover, the diffusion of  $\text{O}^{2-}$  ions in  $\text{CaCl}_2$  inside the granules

153 becomes important when the reduction proceeds. For the reduction along the granule surface, the

154 formed  $\text{O}^{2-}$  ions immediately diffuse into the bulk  $\text{CaCl}_2$ . For the reduction inside, the formed  $\text{O}^{2-}$

ions must diffuse through the crevice of the Si shell. As explained in the previous study,<sup>45,46</sup> the O<sup>2-</sup> ions accumulate in the CaCl<sub>2</sub> in the crevice, leading to an increased viscosity of CaCl<sub>2</sub> and decreased diffusion coefficient of the O<sup>2-</sup> ions. Consequently, the reduction rate decelerates with the progress of electrolysis, which is predominantly responsible for the behavior of  $F_{\text{act}}$ .

**Apparent Current Density.**— The current density, an important kinetic index, is evaluated from the weight change of the samples. The electrochemical reduction of SiO<sub>2</sub> is written as

The quantity of cathodic electric charge ( $Q$ ) used for the reduction of SiO<sub>2</sub> can be calculated by

$$Q = \frac{W_{\text{bef.}} - W_{\text{aft.}}}{2M_{\text{O}}} \times 4e \cdot N_{\text{A}} \quad (4)$$

where  $e$  is the elementary charge of an electron ( $e \approx 1.6 \times 10^{-19}$  C), and  $N_{\text{A}}$  is Avogadro's constant ( $N_{\text{A}} \approx 6.02 \times 10^{23} \text{ mol}^{-1}$ ). The apparent current density ( $J$ ) based on the geometric area of the bottom conductor (Si plate in Figure 1) can be obtained by

$$J = \frac{Q}{A \cdot t} = \frac{Q}{\pi \cdot \frac{d^2}{4} \cdot t} \quad (5)$$

where  $A$  is the valid geometrical area of the Si plate,  $d$  is the inner diameter of the Al<sub>2</sub>O<sub>3</sub> tube ( $d = 0.9$  cm), and  $t$  is the electrolysis time. In the present study, cathodic charge and current are taken as positive values.

The calculated apparent current density is listed in Table II, and its time dependence is shown in

173 Figure 8. The current density was as large as  $0.7 \text{ A cm}^{-2}$  at the initial stage, ca. 20 min, and  
174 gradually decreased with the progress of electrolysis. This value is comparable to the current  
175 density of the commercial Hall-Héroult process for aluminum production.<sup>47</sup> This result indicates  
176 that the direct electrochemical reduction of  $\text{SiO}_2$  in molten  $\text{CaCl}_2$  has the potential of being a highly  
177 productive silicon production process.

178

## 179 Conclusions

180 The kinetic characteristics of the electrochemical reduction of  $\text{SiO}_2$  granules in molten  $\text{CaCl}_2$  at  
181 1123 K were investigated by direct observation of cross-sectioned samples and weight change of  
182 samples during electrolysis.. The results indicated that the reduction was fast at the initial stage of  
183 electrolysis and gradually slowed as the electrolysis progressed. The apparent current density  
184 reached  $0.7 \text{ A cm}^{-2}$  at the initial stage of electrolysis. The direct electrochemical reduction of  $\text{SiO}_2$  in  
185 molten  $\text{CaCl}_2$  has the potential of being a silicon production process with high productivity  
186 comparable to the commercial Hall-Héroult process.
